COVER CROP VARIETY TESTS IN TENNESSEE

2019 - 2020

Experimental Procedures

Cover crop variety tests were conducted at the East Tennessee (Knoxville; ETREC), Middle Tennessee (Spring Hill; MTREC), and Milan (Milan; RECM) AgResearch & Education Centers (**REC**). All locations were planted with a drill to a length of 30 ft. Plot widths varied slightly by location based on equipment. Plots were planted at ETREC in 8 rows on 7.5 in. spacing, at MTREC in 7 rows on 7 in. spacing, and at RECM in 10 rows on 7.5 in. spacing. Plots were planted in a randomized complete block design and replicated three times at each location. Varieties were planted at the appropriate seeding depth for each species (Table 1). The trial included varieties within the broader groups of brassicas, cereals, and legumes; however, all varieties were evaluated in a single trial in order to provide a better head-to-head comparison of the many cover crop varieties available. Contact information and websites for seed suppliers are summarized in Table 2.

A September and October planting date were planned for this study; however, due to extreme drought in the fall of 2019, only the earlier planting date was cut. All plots were planted in early to mid-October (Table 3).

Assessment of Ground Cover

Two 15 in. x 15 in. PVC square were randomly placed in each plot and photographed. These photographs were then analyzed for percent green cover using Canopeo software (Oklahoma State University Department of Plant and Soil Sciences, Stillwater, OK). Plots were photographed one month after planting (mid-Nov), in mid-Feb, early April, and early May; however, the height of many of the cereal and brassica species made this method ineffective and these data are not presented.

Assessment of Height

Height of cover crop varieties was measured in November, February, April, and May for species taller than 4 in. Species shorter than 4 in. were not measured but recorded as 1 in. for statistical purposes.

Assessment of Biomass

Cover biomass was measured in a single, randomly selected, 15 in. x 15 in. square area within each plot. Biomass within that square was cut to a height of 1 in. above the soil surface. Biomass was dried to a constant weight and dry matter biomass was calculated on a per acre basis.

Interpretation of Data

The tables on the following pages have been prepared with the entries sorted by group (brassica, cereal, legume), species, and variety. Biomass, cover, and height data were analyzed using the MIXED procedure in SAS v. 9.4 (Cary, NC) with mean separation performed using the Fisher's

Protected LSD (Least Significant Difference) test. All analyses used a mixed model with treatment as a fixed effect and replicate and location as random effects with an alpha level of 0.05 to determine significance. The model for cover also included sample as a random effect. Mean separation letters have been listed next to mean values for each trait. Varieties that have any letter in common within a column are not significantly different at the 5% level of probability. Varieties with performance statistically equivalent to the top performing variety will have an “A” included in the list of mean separation letters next to that entry. Additionally, mean values between the 50th and 75th percentile are highlighted in light orange and above the 75th percentile are highlighted in dark orange.

Results

Sixty varieties were evaluated in the 2019 – 2020 cover crop variety trial (Table 2). Treatments fell into three groups, brassicas (11 varieties), cereals (20 varieties), and legumes (29 varieties). Species with the greatest representation included radish (6 varieties), barley (5 varieties), cereal rye (9 varieties), crimson clover (6 varieties), hairy vetch (5 varieties), and winter pea (7 varieties).

Variety performance is given across locations (Table 4) and for each individual location, Milan (RECM; Table 5), Spring Hill (MTREC; Table 6), and Knoxville (ETREC; Table 7). Variety performance differed significantly among locations ($P < 0.001$). A side-by-side summary of all data is given in tables 8 to 11. While most species performed similarly across locations, the varieties of radish generally exhibited very poor performance at MTREC, while performing above average at the RECM and ETREC locations (Table 8). Crimson clover varieties also exhibited location differences, with all varieties exhibiting above average biomass in April and May at MTREC, while at the RECM and ETREC, fewer varieties were top-performers (Table 8). These differences may have been due to environmental differences among the locations. Both temperature and precipitation immediately prior to planting and during early establishment can have a significant impact on successful cover crop establishment. Among the three locations, MTREC had the largest rain event immediately prior to planting which may account for the better performance of the clovers at this location. However, it is unclear why the Brassica species did not perform well at MTREC. Brassica species tend to be more prone to winterkill; however, the MTREC location had similar average and minimum monthly temperatures to ETREC.

Varieties that had high biomass in April, generally also had high biomass in May. Overall, top performers for biomass (>75th percentile) in both months were dominated by three species, hairy vetch, winter pea, and cereal rye (Tables 4-8).

Top-performers (>75th percentile) for percent cover varied by evaluation month (Table 4). One month after planting, all top-performers for percent cover were cereal species, with the cereals averaging 22% cover, compared with only 9% for brassicas and 4% for legumes. However, by February, legumes were dominating the top, in particular varieties of common, hairy, and woolypod vetch, and winter pea. In February, legumes averaged 31% cover, compared to 21% in brassicas, and 24% in cereals.

Height may be important for producers interested in grazing cover crops. Cereal varieties were among the tallest in all four evaluation months (Table 4). In April, some brassica species were also included in the top 25% for height, due primarily to the rapid elongation of flowering stalks. By May, several legumes were also in the top 25% for height; however, the “A group” was still dominated by the cereals, with a maximum height of 60 in.

Significant differences were observed among varieties within species. Within top-performing species, cereal rye exhibited the greatest difference in biomass between top and bottom performing varieties, with a difference of 0.9 DM tons/ac in April and 1 DM ton/ac in May. This was also true for hairy vetch varieties, with a difference in top and bottom performing varieties of 0.5 DM tons/ac in April and 0.7 DM tons/ac in May. For winter pea, varieties differences were less pronounced in April (0.2 DM tons/ac), but increased by May (0.6 DM tons/ac).

Overall, results from this trial illustrate the variation both among species and among varieties within species as well as highlight top-performing varieties for East, Middle, and West Tennessee.
